Submitted to ApJ.

ABSTRACT

We propose to describe the variety of galaxies from the Sloan Digital Sky Survey (SDSS) by using only one affine parameter. To this aim, we construct the Principal Curve (P-curve) passing through the spine of the data point cloud, considering the eigenspace derived from Principal Component Analysis (PCA) of morphological, physical and photometric galaxy properties. Thus, galaxies can be labeled, ranked and classified by a single arc length value of the curve, measured at the unique closest projection of the data points on the P-curve. We find that the P-curve has a "W" letter shape with 3 turning points, defining 4 branches that represent distinct galaxy populations. This behavior is controlled mainly by two properties, namely $u - r$ and SFR (from blue young at low arc length to red old at high arc length), while most of other properties correlate well with these two. We further present the variations of several important galaxy properties as a function of arc length. Luminosity functions variate from steep Schechter fits at low arc length, to double power law and ending in Log-normal fits at high arc length. Galaxy clustering shows increasing autocorrelation power at large scales as arc length increases. Cross correlation of galaxies with different arc lengths shows that the probability of 2 galaxies belonging to the same halo decreases as their distance in arc length increases.

PCA analysis allowed to find peculiar galaxy populations located apart from the main cloud of data points, such as small red galaxies dominated by a disk, of relatively high stellar mass-to-light ratio and surface mass density. On the other hand, the P-curve helped understanding the average trends, encoding 75% of the available information in the data.

The P-curve allows not only dimensionality reduction, but also provides supporting evidence for relevant physical models and scenarios in extragalactic astronomy:

1) Evidence for the hierarchical merging scenario in the formation of a selected group of red massive galaxies. These galaxies present a log-normal r-band luminosity function, which might arise from multiplicative processes involved in this scenario.

2) Connection between the onset of AGN activity and star formation quenching as mentioned in Martin et al. (2007), which appears in green galaxies when transitioning from blue to red populations.

1. INTRODUCTION

In order to constrain the physical processes driving galaxy evolution, it is common practice to measure a number of physical properties for a set of galaxies, and then investigate the correlations between these parameters. In this context, galaxy surveys have become more and more appropriate. The number of galaxies available is getting larger, and the amount of information to constrain physical properties is also increasing, yielding to more accurate estimates. The level of precision of these estimates is also likely to increase in the future, either with the combination of wide angle surveys observing at different wavelengths, or with panchromatic surveys using large number of filters (e.g. PAU, Benítez et al. 2009), which will benefit from multiband imaging for millions of galaxies. As this data deluge is turning as-

tronomy into becoming a data-intensive or e-science (see Hey et al. 2009), one is confronted with the issue of being just able enough to analyze the feature space, whose dimensionality keeps on increasing. In face of such large amount of physical properties, one wants to find the minimal and most important set which describes galaxies accurately. In this context, a common approach used to reduce the dimensionality of these dataset is performing a Principal Component Analysis (PCA, also known as Karhunen-Loève transform; see e.g. Efsthathiou & Fall 1984; Murtagh & Heck 1987). PCA enables us to find an uncorrelated and orthonormal set of linear combinations of properties (eigenvectors) that describe optimally the correlations and variation of the data. This approach has been fruitfully used in astronomy to classify galaxy and quasars based on their spectra (Connolly et al. 1995; Yip et al. 2004a,b). PCA has been applied on a wider basis using various galaxy properties such as the equivalent width of emission lines (Györy et al. 2011) or a mix of spectral and morphological features (Coppa et al. 2011) to help characterizing the galaxy population. PCA also showed useful for instance when applied to stellar synthe-

sis population models to derive galaxy physical parameters (Chen et al. 2011). PCA does not however, enable to capture all the information contained in the input sample. It is by nature linear, and hence can not describe non linear correlations within the data. Other methods, such as applying locally linear embedding to galaxy spectra (Roweis & Saul 2000; Vanderplas & Connolly 2009), enable to take into account non linearities, as they map high dimension data onto a surface, while preserving the local geometry of the data.

In this paper, we introduce the principal curve (P-curve, see e.g. Einbeck et al. 2007, for a review), which can be seen as a nonparametric extension of linear PCA. The principal curve is the curve following the location of the local mean in the multi-dimensional cloud of data points. In practice, the P-curve can be conveniently built in the PCA eigenspace spanned by the most important eigenvectors along which the variance is highest. The important fact here is that every data point can be assigned a unique closest projection onto the curve, and be labeled by the arc length value measured from the beginning of the curve to the projection. This reduces the complexity of multi dimensional data effectively into only one dimension. Moreover, the ranking of galaxies according to their associated arc length values provides a natural and objective way of ordering, partitioning and classifying the rich zoo of galaxies in the nearby universe.

In this paper, we take advantage of the wealth of data and build the principal curve for both physical and photometric properties belonging to the low redshift Main Galaxy Sample (MGS) (Strauss et al. 2002) in SDSS (Stoughton et al. 2002). Since the MGS is flux limited, the Malmquist bias underestimates the volume density of faint galaxies compared to that of brighter ones. As a result, the common practice of performing a simple PCA for all galaxies does indeed provide a biased result toward the behavior of the properties of bright objects. As a solution, we do not restrain the statistics by constructing a much smaller volume limited sample, but keep all galaxies by assigning them weights with which we perform Weighted PCA (WPCA) and P-curve methods. We then investigate how the arc length associated to each galaxy correlates with a number of photometric, spectroscopic and physical galaxy properties, as well as morphology, mean spectra, and a first (luminosity function) and second (clustering) moments of galaxies. Our results show that the arc length values remarkably encode a large number of well-known trends in the local Universe.

This paper is organized as follows: in Section 2 we present the dataset we use. Section 3 details the galaxy properties we include in our PCA analysis. Section 4 presents the methods we use for the dimensionality reduction, weighted PCA and principal curve. We detail in Sec. 5 how we build the principal curve from the SDSS data. In Section 6 we present our results and discuss them in Sec. 7.

We use in this paper a flat Λ cosmology assuming $\{\Omega_\Lambda, \Omega_M, h_0, w_0\} = \{0.7, 0.3, 0.7, -1\}$.

2. THE GALAXY SAMPLE

In this paper we use photometric and spectroscopic data of galaxies from SDSS-DR8 (Aihara et al. 2011), available in a MS-SQL Server database queried online

via CasJobs³.

In particular, we use the Main Galaxy Sample (MGS) (Strauss et al. 2002). These galaxies constitute a flux limited sample, with an r-band petrosian apparent magnitude cut of $m_r \leq 17.77$, and a redshift distribution peaking at $z \sim 0.1$. Their spectra covers the rest frame range of 3800-8000Å, with a resolution of 69 km s⁻¹pix⁻¹.

Several selection cuts and flags were enforced in order to have a clean sample. We selected only **science primary** objects appearing in calibrated images having the **photometric** status flag. Also, we selected imaging fields where $0.6 \leq \text{score} \leq 1.0$, which assures good imaging quality with respect to the sky flux and the PSF's width. Furthermore, we neglected individual objects with bad deblending (with flags **PEAKCENTER**, **DEBLEND_NOPEAK**, **NOTCHECKED**) and interpolation problems (**PSF_FLUX_INTERP**, **BAD_COUNTS_ERROR**) or suspicious detections (**SATURATED_NOPROFILE**)⁴. Also, we chose galaxies whose spectral line measurements and properties are labeled as **RELIABLE**.

The sky footprint of the clean spectroscopic survey builds up from a complicated geometry defined by **sectors**, whose aggregated area covers $\sim 7930\text{deg}^2$ or a fractional area $F_A \simeq 0.192$ of whole sky. We choose a redshift window of $[z_1, z_2] = [0.02, 0.08]$. The lower limit avoids including large photometrically-cumbersome galaxies on the sky, and the upper limits reduces the amount of evolution of galaxy properties ($\Delta t < 0.78\text{Gyr}$), while keeping the statistics high. Redshift incompleteness arises from the fact that two 3" aperture spectroscopic fibers cannot be put together closer than 55" in the same plate. As an strategy, denser region in the sky are given a greater number of overlapping plates. Nevertheless, 7% of the initial galaxies photometrically targeted as MGS didn't have their spectra taken.

We further construct a magnitude limited sample, on which we will center our main study. Here, extinction-corrected petrosian apparent magnitude cuts of $[m_{r,1}, m_{r,2}] = [13.5, 17.65]$ are applied. The lower limit is set due to the arising cross talk from close fibers in the spectrographs, when they contain light from very bright galaxies. The upper limit safely avoids the slight variations of the limiting apparent magnitude around 17.77 over the sky in the targeting algorithm. This leaves us with 174,266 galaxies.

A volume limited subsample was also created, being a subset of the previous magnitude limited sample. This subsample is used for the study of spatial correlation functions in Sec. 6.4. The redshift ranges are $[z_1, z_2] = [0.02, 0.05]$, with an absolute magnitude window of $[M_{r,1}, M_{r,2}] = [-21.19, -19.08]$, which leave us with $\sim 40,000$ galaxies.

3. SELECTING GALAXY PROPERTIES

Galaxies present a variety of physical, spectroscopic and 5-band photometric properties made available in the SDSS-DR8 data catalog. We selected the most relevant in order to create a p-Dimensional cloud of properties or features for further study.

Within the photometry-derived properties included are

³ <http://casjobs.sdss.org>

⁴ Detailed explanation in `\protect\protect\protect\edef0T1{0T1}\let\enc0`

the colors, which show the coarse shape of galaxy spectra, and in some extend the age of the overall stellar population in the galaxy. Only the colors $u-r$ and $g-r$ were selected, since most of the color combinations possible from the u, g, r, i, z bands (Fukugita et al. 1996) are highly correlated. For computing colors, extinction-corrected model magnitudes (Stoughton et al. 2002) were used, as well as k-corrections to an observing rest-frame of $z = 0$. The k-corrections are calculated by using a template fitting technique used in e.g. Budavári et al. (2000) and Csabai et al. (2000). Here, the colors are matched to the colors of a model spectrum defined by a non negative linear combination of redshifted template spectra. Then, the best model spectrum is blueshifted back to the rest frame ($z=0$) and the k-correction computed. The template spectra are drawn from a list provided by Bruzual & Charlot (2003).

Since we will study the luminosity function as a function of position in this cloud (Section 6.3), we decided not to include the absolute magnitude M_r as a property. If we did, any partitioning of the cloud would introduce non-desired artificial cuts in the range of absolute magnitudes used in the computation of luminosity functions. Therefore, neither the absolute magnitude nor any other strongly correlated property of it (such as stellar mass) should be chosen as part of the properties.

Another photometry-derived feature is the concentration index $C \equiv R90_r/R50_r$, where $R90_r$ and $R50_r$ are the radii enclosing the 90 and 50% of the r-band petrosian flux, respectively. This index has been found to correlate with galaxy morphological type (Strateva et al. 2001; Shimasaku et al. 2001). Indeed, de Vaucouleurs light profiles of elliptical galaxies are more concentrated than the exponential profile in the disks of spiral galaxies.

The redshift-dependent r-band surface brightness defined by $\mu_{50,r} = m_r + 2.5 \log[2\pi R50_r^2(1+z)^4]$ is also included as a property. This breaks the degeneracy of $R90_r/R50_r$ between bright and dim spiral galaxies. Here we use the extinction and k-corrected petrosian apparent magnitude m_r , taking $\sqrt{2}R50_r$ as a less noisy proxy for the petrosian radius (Stoughton et al. 2002; Strauss et al. 2002).

The physical properties selected are the star formation rate (SFR), specific star formation rate (SFR/ M_* , where M_* is the stellar mass) and petrosian r-band mass-to-light ratio (M_*/L_r). These are included in SDSS-DR8 and obtained from galaxy spectra analysis at MPA and JHU⁵, as detailed in Kauffmann et al. (2003a), Brinchmann et al. (2004), Tremonti et al. (2004), Gallazzi et al. (2005) and Salim et al. (2007).

Note that M_* has been derived from template fitting to the total flux in the 5 photometric bands (Aihara et al. 2011). As the spectral fibers diameter cover only $3''$ of the central part of each galaxy, the SFR had to be corrected for this deficiency to its full value (Brinchmann et al. 2004).

Since other spectral features such as lick indices or line equivalent widths are non-trivial to extrapolate from their fiber values to the full galaxy ones, we do not include these in the building of the cloud of properties. We do, however, study them apart in Sections 6.2 and 7.

4. METHODS FOR DIMENSIONALITY REDUCTION

Most of the time, data-mining deals with the data point matrix $\mathbf{A} = [\mathbf{A}^1 \mathbf{A}^2 \dots \mathbf{A}^p] \in \mathbb{R}^{N \times p}$, composed by the columns $\{\mathbf{A}^i\}_{i=1}^p$ that contain N observations for each of the p properties or features. Thus $\mathbf{A}$ can then be thought as a length- N realization of the random vector $\mathbf{X} = [X_1 \dots X_p] \in \mathbb{R}^p$ with distribution $D_{\mathbf{X}}(\mathbf{x})$.

In our work, dimensionality reduction is used for explaining the variations of $\mathbf{X}$ as function of only 1 parameter. For that effect, we use Weighted PCA and Principal Curves, whose detailed descriptions are included in Sections 4.1 and 4.2.

4.1. Weighted PCA (WPCA)

Principal Components Analysis (PCA) (Pearson 1901; Jackson 1991; Jolliffe 2002), also known as Karhunen-Loeve Transform, is a widely used method for dimensionality reduction and classification. It can be seen as a transformation involving a translation, linear scaling and rigid rotation of a collection of N p -dimensional data points onto a new coordinate system. The new orthonormal axes, or principal components $\{\mathbf{PC}_i\}_{i=1}^p \in \mathbb{R}^{N \times 1}$, are constructed such that the projections of the data points on the $\mathbf{PC}_i$ s are uncorrelated. $\mathbf{PC}_1$ is selected as the axis on $\mathbb{R}^p$ which has the highest possible variance of the points projected onto it. The next $\mathbf{PC}_i$ s are ordered in descending value of the variance, having $\mathbf{PC}_p$ the lowest. Thus, dimensionality reduction is attained by describing the data in terms of the most important principal components (Hastie et al. 2009). This can be obtained by considering only the space spanned by the first $q \leq p$ variance-ranked eigenvectors whose cumulative variance reaches above a high enough threshold.

In practice, the PCs and their variances can be found using singular value decomposition (SVD) of the covariance matrix $\mathbf{C}$ of the data points (Golub & Van Loan 1996). SVD allows us to factorize it in the form $\mathbf{C} = \mathbf{V}\mathbf{\Sigma}\mathbf{V}^T$. Here, $\mathbf{\Sigma}$ is a diagonal matrix with the eigenvalues (variances) and $\mathbf{V}$ contains the eigenvectors (principal components) in the respective columns. Thus, $\mathbf{V}$ contains the expansion coefficients of the transformation $\mathbf{PC}_i = \sum_{j=1}^p \mathbf{V}_{ji} \mathbf{x}_j$ ($i = 1, \dots, p$) from property space to PC space.

In Weighted PCA, the covariance matrix is calculated in a weighted schema. Many times we are confronted with noisy or missing data points. As a solution, we can assign a weight $w_i > 0$ to each i th data point in order to account for the noisy data points or the missing ones. In this context, WPCA involves considering these weights in the calculation of all averages and covariances between the p properties. In general, the properties might have different units, for which they have first to be made unitless by standardization of the data points (subtract to each property its (weighted) average and then divide it by its (weighted) standard deviation).

4.2. Principal Curves

Principal curves (P-curves) and surfaces (P-surfaces) (Hastie 1984; Hastie & Stuetzle 1989; Tibshirani 1992; Gorban et al. 2008) go one step ahead of PCA, providing a low-dimensional *curved* manifold that passes through the middle of the data points. In this paper we consider a 1-parameter (called l) principal curve $\mathbf{f}(l) =$

⁵ <http://www.mpa-garching.mpg.de/SDSS>

$[f_1(l), \dots, f_p(l)] \in \mathbb{R}^{N \times 1}$, where each of the N data points $\mathbf{x} = [x_1 \dots x_p]$ is given a unique closest projection $\mathbf{f}(l_f(\mathbf{x}))$ onto the curve. As a convention, $l_f(\mathbf{x})$ is chosen to be the arc length from the beginning of the curve to the projection point of $\mathbf{x}$. Under this context, the P-curve can be considered by itself the 1st and only *curved* principal component, as the dimensionality of the data is reduced from p to 1 dimension. In practice, the P-curve is composed by $N - 1$ line segments that connect the projection points.

The principal curve is defined as the *average* of the data-points that project onto it, minimizing the projection distance between $\mathbf{x}$ and $\mathbf{f}(l_f(\mathbf{x}))$ over all points. This property of self consistency allows us to follow a series of iterative projection-expectation steps for its construction (Hastie & Stuetzle 1989). In fact, an educated first guess for the P-curve is to make it equal to $\mathbf{PC}_1$. Later on, the j th estimate $f_i^{(j)}(l)$ of the curve at the j th expectation step is calculated as $f_i^{(j)}(l) = E(\mathbf{X}_i | l_{f^{(j-1)}}(\mathbf{X}) = l)$. In practice, we compute this expression using a weighted penalized cubic B-spline regression (Silverman 1985; Hastie & Tibshirani 1990; Ruppert et al. 2003; Hastie et al. 2009). These splines are calculated on a series of k knots chosen from the data points, while the degrees of freedom (df) of the regression control the degree of smoothing of the P-curve. On the other hand, the j th projection step is performed next, involving the search for the closest perpendicular projection of $\mathbf{x}$ onto $\mathbf{f}^{(j)}(l)$, which is composed by the $N - 1$ line segments. The iterations stop when the cumulative projection distances from the data points to the P-curve do not change significantly with respect to the one in the previous step.

Although P-curves are constructed on the p -dimensional space of properties, we can consider building the P-curve of the data points projected on the first q most important principal components of the WPCA. This minimizes the complexity and computations, specially in the case $p \gg q$, without losing much information. The approximation is of course valid as long as the first q eigenmodes contain as much of the total variance as possible.

5. BUILDING THE PRINCIPAL CURVE AND POPULATION SEPARATORS ALONG ARC LENGTH

5.1. $V_{\max}$ weighting

As the MGS is a magnitude limited sample, not all galaxy types are sampled equally in the survey volume. As a consequence, we used WPCA and a weighted principal curve of the galaxy population to get an unbiased result.

In detail, at higher redshifts we sample mostly the brightest galaxies, neglecting the faint ones (Malmquist bias). On the other side, at low redshifts the SDSS spectrograph fails to take the spectra of very bright galaxies (see Section 2).

As a solution, we use the $V_{\max}$ weighting method (Schmidt 1968) to account for this incompleteness. Here, each i -th galaxy is assigned a weight $w_i = V_s / V_{\max,i} \geq 1$, where V_s is the volume of the survey. Here we note that, given the particular $[z_1, z_2]$ and $[m_1, m_2]$ intervals for the survey, the i -th galaxy found at z_i could be observed only within a maximum comoving volume $V_{\max,i} \leq V_s$.

If the i -th galaxy of apparent magnitude m_i , k -correction $k_i = k(z_i)$, and at a luminosity distance $D_L(z_i)$ were to have limiting apparent magnitudes $m_{1,2}$, then it should be moved to a limiting luminosity distance $D_{L,i}(m_{1,2})$ given by

$$D_{L,i}(m_{1,2}) \equiv D_{L,i}(z_{\text{lim}}; m_{1,2}) \\ = D_L(z_i) \times 10^{(m_{1,2} - k(z_{\text{lim}}) - m_i + k_i)/5}. \quad (1)$$

Hence, the maximum volume is defined by the biggest interval of D_L inside which a galaxy can appear in the survey:

$$V_{\max,i} = [V(\min(D_L(z_2), D_{L,i}(z_{\text{lim}}; m_2))) \\ - V(\max(D_L(z_1), D_{L,i}(z_{\text{lim}}; m_1)))] \times F_A, \quad (2)$$

As Eq. (1) defines z_{lim} in an implicit way, we solve for it iteratively. We calculated the $V_{\max}$ values directly inside the database using an integrated cosmological functions library (Taghizadeh-Popp 2010).

The PCA, P-curve and calculations related to volume densities in this paper (such as histograms) are all $V_{\max}$ weighted.

5.2. WPCA results

As measure for not skewing the PCA, we clipped off visually the outliers in each of the $p = 7$ galaxy properties in order to dismiss artifacts or wrong measurements. We also used only galaxies which have all the 7 properties measured, simplifying the calculations and avoiding using Gappy PCA (Connolly & Szalay 1999). This left us with a total of $N = 171,698$ galaxies (99% of the initial ones).

FIG. 1.— The $\mathbf{V}$ matrix resulting from applying WPCA on the 7 galaxy properties. The columns are the orthonormal principal components (i.e. eigenvectors of the covariance matrix). Each $\mathbf{PC}_i$, $i = 1, \dots, 7$ can be viewed as a linear combination of properties, with the expansion coefficients $\mathbf{V}_{ji}$ of the j th property stored in the j th row. Coefficients with stronger color show a higher importance of the property for the given PC. The sign of the coefficient shows correlations/anticorrelations between the properties and the PC.

Figure 1 and Table 1 present the results from computing WPCA on the 7 galaxy properties. From Table 1, we can notice that most of the information (97% of the total variance) is contained in the first 4 principal components. On Fig. 1, each $\mathbf{PC}_i$, $i = 1, \dots, 7$ can be viewed as a linear combination of properties, with the expansion coefficients $\mathbf{V}_{ji}$ of the j th property stored in the j th row. Coefficients with stronger color show a higher importance of the property for the given PC. The sign of the coefficient shows correlations/anticorrelations between the properties and the final value of the PC.

FIG. 2.— Principal curve (black continuous line) fitted to the first 4 principal components (density maps are log-scaled, with contour curves separated by 0.5 dex). The arc length increases in the direction of increasing $\mathbf{PC}_1$. The first and last 15 data points (ordered by arc length) are connected to their corresponding projections on the curve with dashed lines. The separators between the $\{L_i\}_{i=1}^{20}$ groups are shown as black circles on top of the curve (see text). The curve presents 3 turning points marked as brown rings. The colored arrows show the directions and relative strength of the galaxy properties projected onto PC space. In $\mathbf{PC}_3$ v/s $\mathbf{PC}_4$, we plotted the separating line between the main cloud and a small blob of galaxies, given by $\mathbf{PC}_4 \leq -1.3 + 0.55(\mathbf{PC}_3 - 2.0)$ (see Sec. 6.5.1).

TABLE 1
WPCA VARIANCES

	$\mathbf{PC}_1$	$\mathbf{PC}_2$	$\mathbf{PC}_3$	$\mathbf{PC}_4$	$\mathbf{PC}_5$	$\mathbf{PC}_6$	$\mathbf{PC}_7$
$\sigma_{\mathbf{PC}}^2$	4.493	1.115	0.842	0.363	0.090	0.068	0.030
$\sum \frac{\sigma_{\mathbf{PC}}^2}{p}$	0.642	0.801	0.921	0.973	0.986	0.996	1.000

Variance for each principal components and its associated cumulative variance. Since the data has been standardized, the sum of the variances is equal to the number of dimensions ($p = 7$).

For $\mathbf{PC}_1$, the strength (absolute magnitude) of its expansion coefficients $\mathbf{V}_{j1}$ in the basis of the galaxy properties is shared mostly evenly between these properties, being $u - r$, $g - r$, SFR/M_* and M_*/L_r the most important. The correlations show that high values of $u - r$, $g - r$, M_*/L_r and $R90_r/R50_r$, together with low values of $\mu_{50,r}$, SFR/M_* and SFR , will produce a high $\mathbf{PC}_1$ value. We might therefore expect that $\mathbf{PC}_1$ is a good separator between the young, blue population of spirals/irregulars and the old population of red old ellipticals.

For $\mathbf{PC}_2$, the SFR and $\mu_{50,r}$ are the most important, having opposite signs. Thus, we expect galaxies with bright surface brightness and high star formation to show high values of $\mathbf{PC}_2$.

For $\mathbf{PC}_3$, the most important property is $R90_r/R50_r$,

with an opposite correlation with respect to the next important properties of mostly equal strength ($u - r$, $g - r$, SFR , M_*/L_r and $\mu_{50,r}$). We can expect that big and bright star-forming spiral galaxies with reddish colors (probably from a red core) should have high $\mathbf{PC}_3$.

For $\mathbf{PC}_4$, all the properties have the same correlations, being $\mu_{50,r}$, $R90_r/R50_r$ and SFR the most important. Thus, concentrated (and possibly star-forming) galaxies of faint surface brightness have high values of $\mathbf{PC}_4$. As the variance along $\mathbf{PC}_4$ is much smaller than the previous PCs, this is a rare combination of correlation for these properties to be observed at the same time.

Furthermore, the last 3 PCs ($\mathbf{PC}_5$, $\mathbf{PC}_6$ and $\mathbf{PC}_7$), which account for less than 2% of the total variance, are less obvious to interpret. They might trace either special cases of galaxy populations, or just artifacts and wrong/noisy measurements of the properties.

5.3. The fitted Principal Curve and Population Separators along it

We decided to construct the Principal curve in the 4-dimensional space defined by $\{\mathbf{PC}_1, \dots, \mathbf{PC}_4\}$, since their combined cumulative variance (0.973) is close to unity (see Table 1). Although the computation for the number of dimensions and data points involved is not too intensive, we think of this as a pedagogical example that can be used for other extreme cases when $N \geq 10^{10}$ objects with $p \geq 100$ dimensions, for instance. In fact, our elec-

FIG. 3.— Probability density of the arc-length values $\{l_i\}_{i=1}^N$ measured at the points of the curve where the N data points are projected onto. The arc-length increases in the direction of increasing $\mathbf{PC}_1$. Vertical black continuous lines denote the population separators, while the numbers denote the $\{L_i\}_{i=1}^{20}$ galaxy groups. The 5 small tick marks within each galaxy group mark the boundaries of the subgroups $\{\lambda_1, \dots, \lambda_{100}\}$.

FIG. 4.— Density maps of the principal components (y-axis) as a function of the arc-length l (x-axis). Density is log-scaled, contour curves separated by 0.5 dex. Population separators are shown as vertical tick marks. The numbers denote the $\{L_i\}_{i=1}^{20}$ galaxy groups. Colored vertical lines show the position of the maxima and turning points at particular l values.

tion does not change significantly the results compared to using $p = 7$.

In the expectation step for creating the principal curve, each $\mathbf{PC}_i$ is fitted with penalized B-splines of 5.4 degrees of freedom (df), defined at a sequence of $k = 211$ unique knots chosen at equally spaced quantiles of arc-length values. Principal curves with $df \gtrsim 7$ make the curve to oscillate excessively, turning back and forth across and along $\mathbf{PC}_1$, whereas with $df \simeq 4$ resemble more closely a straight line along the $\mathbf{PC}_1$ direction.

Figure 2 shows the result of fitting the principal curve to $\{\mathbf{PC}_1, \dots, \mathbf{PC}_4\}$. The 4-dimensional cloud of properties presents 2 density maxima placed mainly along the $\mathbf{PC}_1$ direction, corresponding to the blue and red galaxy populations. The principal curve mostly resembles the letter "W", presenting clearly 4 different regimes or branches separated by 3 turning points (T-points).

We created 20 equal number density galaxy groups (in Mpc^{-3}) labeled as $\{L_i\}_{i=1}^{20}$ by placing population separators at fixed arc length values along the P-curve, as

shown in Figures 2 and 3. Galaxies are grouped together into the same L_i group when the arc length values measured at their projections points onto the P-curve are placed between 2 consecutive separators. These separators are positioned in such a way that the (V_{max} -weighted) number density (in Mpc^{-3}) of the galaxies belonging to each of the 20 L_i groups amounts to 1/20th of that from the whole sample of galaxies. This allowed us to study the 4 principal curve branches in detail. We chose the arc-length to increase in the same direction of increasing $\mathbf{PC}_1$, with growing values of arc length as we progress from L_1 to L_{20} . Thus, the P-curve's 1st branch is comprehended in $\{L_1, \dots, L_6\}$, the 2nd branch in $\{L_7, \dots, L_{14}\}$, the 3rd branch in $\{L_{15}, \dots, L_{18}\}$ and the 4th branch in $\{L_{19}, L_{20}\}$. Table 2 shows some statistics of these groups.

Within each L_i group, we further created 5 subgroups of galaxies along arc length naming them $\{\lambda_i\}_{i=1}^{100}$, also of equal number density in Mpc^{-3} as explained before. We further partitioned these groups similarly, now using several radial separators in the perpendicular direction to the curve, defining 10 concentric cylinder-like separating surfaces. In this way, the groups defined by this finer partitioning have all the same number density (in Mpc^{-3}), equal approximately to 1/1000th of the number density of the whole sample. This allowed us to identify and extract localized galaxy populations positioned very close to the spine of the cloud of properties, and study them in Sec. 6.5.2.

Figure 3 shows the probability density distribution of the arc-length l values, as well as the population separators. The curve has a length of $l_{\text{max}} = 20.24$, and the variance of the arc length values is $\sigma_l^2 = 7.79$, measured with respect to the center of the curve at $\langle l \rangle = 7.91$. Note that Table 2 shows that the quadratic mean (root mean square) of all the projection distances from the data points to the P-curve takes a value of $d_{\perp} = 1.31$, which is small compared to the length of the curve. The blue and red peaks of maximum density are clearly visible, as well as a small green peak. The 1st turning point (at L_6) lies closely with the blue maximum (L_7), whereas the red maximum (L_{17}) is a little behind of the 3rd T-point (L_{18}), after which we can find a hump defining the red sequence of galaxies. We find a green maximum (L_{16}) standing in between the 2nd T-point (L_{14}) and the red

maximum.

Figure 4 shows the density maps of the scatter of each $\{\mathbf{PC}_1, \dots, \mathbf{PC}_4\}$ as a function of the arc-length. The different shapes that this scatter presents depend evidently on the contortions or twists of the principal curve along the PCs. As the 4 branches of the curve mostly turn left and right along $\mathbf{PC}_2$, the scatter in $\mathbf{PC}_2$ show the same "W" shape as the P-curve. On the other hand, the curve increases its length into the $\mathbf{PC}_1$ direction, so the scatter shows a mostly linear relation between $\mathbf{PC}_1$ and arc length. The same analysis applies to the scatter of the next PCs, which is boomerang-shaped for $\mathbf{PC}_3$ and mostly constant with respect to arc-length for $\mathbf{PC}_4$ (although with little wiggles).

TABLE 2
STATISTICS OF THE $\{L_i\}_{i=1}^{i=20}$ GALAXY GROUP.^a

^a N_{gal} denotes the number of galaxies in each group, comprehended in the arc length interval $[l_{min}, l_{max}]$ of $\langle l \rangle$ average arc length. The value $d_{\perp}$ denotes the quadratic mean (root mean square) of the projection distances from the data points onto the P-curve.

6. GALAXY PROPERTIES AND STATISTICS AS FUNCTION OF ARC LENGTH

In this section we show how galaxy properties, luminosity functions and spatial clustering change as a function of the $\{L_i\}_{i=1}^{i=20}$ equal number density galaxy groups (ordered in ascending arc-length).

Compared to $\mathbf{PC}_1$ alone, the principal curve provides much more information about particular changes in properties along its arc length. We will see that the evolution of galaxy properties along the curve is intimately related to the "W" shape of the principal curve, where each of the 4 branches define particular galaxy populations.

6.1. Morphology and Average Spectra

Figure 5 shows the most representative galaxy morphologies and average spectra for the $\{L_i\}_{i=1}^{i=20}$ groups.

The most evident feature is the change in color and the slope of the spectra (from blue to red), as well as an overall weakening of emission lines (e.g. Balmer series of Hydrogen and forbidden lines, such as OIII, OII, NII,

etc.) and an increase of metallic absorption lines and bands (Na, Mg, H, K, G) as we reach high arc length values. In the same way, morphological types include various types of blue galaxies at the beginning and middle of the curve, whereas red ellipticals dominate the end of it. This bimodality is expected and agrees with $\mathbf{PC}_1$ in Fig. 1, appearing also other studies as the change along the 1st principal component (e.g. Yip et al. 2004b; Coppa et al. 2011). We can, however, identify as well more subtle populations along arc length, not distinguishable in $\mathbf{PC}_1$ alone. These distinct population are defined on each of the 4 branches of the principal curve, connected by the 3 turning points.

With respect to morphologies, we see that the arc length correlates very well with the Hubble galaxy type. We however miss the distinction between barred/non-barred spiral galaxies due to the lack of properties able to separate them. Blue irregulars and blue compact dwarf (BCD) galaxies (Papaderos et al. 2006; Corbin et al. 2006) appear in the 1st branch of the principal curve. Some of these type of BCDs were identified as the green pea galaxies at higher redshift (Cardamone et al. 2009). These morphologies change then into low surface brightness galaxies (LSBGs) with spiral and irregular shapes, which dominate the 1st turning point and blue maximum. Bright spirals with strong blue star forming arms appear in the second branch, which by the 2nd turning point show sizable bulges. A dramatic change happens in the 3rd branch, where reddish big-bulged spirals and lenticulars dominate, forming part of the green and red maxima. A new transition happens at the 3rd turning point, having the big bright red ellipticals (CDs) and brightest cluster galaxies (BCGs) dominate at the end of the P-curve's 4th branch.

Emission lines, such as the forbidden OII, OIII, SII and NeII, as well as the Balmer series of Hydrogen (e.g. H_{α} , H_{β} , H_{γ}), are strong in the violently starforming blue galaxies at the 1st branch. These lines weaken as we transition into LSBGs, but interestingly H_{α} and H_{β} become stronger in the 2nd branch, reaching maximal values in the starforming spirals at the 2nd turning point. After this, they weaken again to become imperceptible in the bright ellipticals in the 4th branch. NII follows the same pattern as H_{α} , but somehow remains still visible in CD galaxies, as seen in many spectral atlas (e.g. Dobos et al. 2012). On the other hand, OIII declines steadily through arc length, disappearing after the red maximum.

Absorption lines, such as Na, Mg and the G band become evident in the starforming spirals by the end of the 2nd branch (as the bulge increases in size), and appear strong in the ellipticals at the 4th branch. Although the H and K lines of calcium are always visible, the 4000Å break increases steadily with arc length, turning into a striking feature in bright ellipticals.

6.2. Spectral and Physical Properties

Figure 6 shows the evolution of the galaxy properties as a function of arc length in the principal curve, whereas Table 3 contains the average values of the properties at each $\{L_i\}_{i=1}^{i=20}$.

Looking at the 7 properties on which the WPCA was built, the most important feature is that they present the same shape as the $\mathbf{PC}_i$ in which they have the greatest

FIG. 5.— *Top*: Panels with the 4 most representative galaxy shapes that appear in each of the $\{L_i\}_{i=1}^{20}$ galaxy groups. Arc-length increases from L_1 to L_{20} . White bars show the scale in arcseconds. *Bottom*: Average rest-frame spectrum of same 20 groups as above. The flux (y-axis) is normalized to be 1 at $\lambda = 4000$ Å. The average of each group was performed on 1000 galaxies sampled randomly with probabilities proportional to V_{max}^{-1} . Also marked are the positions of emission lines (top row) and absorption lines (bottom row).

FIG. 6.— Galaxy properties (y-axis) as a function of arc-length in the principal curve (x-axis). Properties are ordered row-wise, and grouped with respect to which principal component they look like the most as in Fig. 4 (upper right hand corner of each panel). The **PC₁** case resembles a straight line, **PC₂** a “W” and **PC₃** a boomerang. The black circles at the mean arc length value within each $\{L_i\}_{i=1}^{20}$ group show the position of the median of the distribution of the property in it, together with vertical bars spanning the 15.9% to 84.1% quantiles ($\pm 1\sigma$). The orange and cyan bars show respectively the same quantiles for the red spine and red spiral blob galaxies discussed in Sec. 6.5.

behaves differently to the other emission lines (such as Balmer series) due to the higher ionization degree. The arc length also correlates linearly with *e*class, which is the classification parameter derived in the PCA of galaxy spectra in Yip et al. (2004b), defined as a function of the expansion coefficients in the base of the first 2 eigenspectra. In general, these properties can be expressed as a linear combination of each other, as seen in astrophysical use, e.g. $M_*/L = a \times \text{Color} + b$ (e.g. Baldry et al. 2004).

In the same way, $\log SFR$ and $\mu_{50,r}$ resemble strongly the "W" shape of PC_2 . Some emission lines belonging to this group are NII and $H\alpha$, the latter being a well known proxy for SFR (Kennicutt 1998). Also, M_r is a good proxy for $\log M_*$ (Bell et al. 2003), both of which related to $R_{90,r}$ and $\mu_{*,r}$, and seemingly correlate with $\mu_{50,r}$. Interestingly, the shape of the average Lick Na D index is similar to the "W" shape of PC_2 (and SFR), but the larger 1σ dispersion in the average makes it not very significant. Lick Na D is expected to represent a strong absorption feature in old stellar populations, as shown in the ellipticals at high arc lengths. We can however see that it presents also a relatively high average at the second turning point. This is related to the fact that Na absorption is not only present in stars, but also in the inter stellar medium as a consequence of outflows or winds present in high star-formation spiral galaxies (Chen et al. 2010).

Note that the boomerang shape of $R_{90,r}/R_{50,r}$ is almost identical to PC_3 . Also correlating with the concentration index is fracDev_r (Stoughton et al. 2002), which determines the mixing in the modeling of the light profiles galaxies, between an exponential disk and a de Vaucouleurs $r^{1/4}$ law for the elliptical bulge.

6.2.1. The BPT Diagram

Figure 7 shows the emission-line ratios BPT diagram (Baldwin et al. 1981) of the MGS galaxies, where AGN identification can be done easily. We considered galaxies presenting $H\alpha$, $H\beta$, [NII] and [OIII] emission lines with well measured equivalent widths, of fractional errors smaller than 0.33 and velocity dispersion smaller than 500 km s^{-1} . These cuts make the $L_1 - L_{15}$ groups be reduced to $\sim 90\%$ of their size, going down to 35% for the remaining groups at higher arc length. Since none of these emission lines were included in the building of the WPCA, we overplotted the average location of the $\{L_i\}_{i=1}^{20}$ groups.

The average locations of the groups can be seen to be connected by a two-branched track in line-ratio space. The left branch covers the region of star forming galaxies, whereas the right branch crosses the separator of Kauffmann et al. (2003b) into the region filled by AGNs. Interestingly, the joining point between the 2 branches happens at L_{14} , which contains the 2nd turning point in the principal curve. This is a striking feature, as it shows that the P-curve is powerful enough to describe galaxy properties beyond the ones included in its construction.

6.3. Luminosity Functions

Figure 8 shows the luminosity function (LFs) corresponding to the $\{L_i\}_{i=1}^{20}$ equal number density groups. They can be directly compared to the evolution of M_r as a function of arc-length in Fig. 6. The LFs were

FIG. 7.— BPT diagram of the MGS galaxy sample. Symbols connected with straight lines track the positions of the average $\log[NII]/H\alpha$ and $\log[OIII]/H\beta$ of each $\{L_i\}_{i=1}^{20}$ (1σ dispersion bars also included). Colored dots are a random 2% samples of each group. Dashed and dotted lines show the separators from Kauffmann et al. (2003b) and Kewley et al. (2001), respectively, between pure starforming galaxies (left region), composite (central) and AGN (right).

^a Fittings to Eqns. 3 and 4. The parameters in Magnitude-space can be expressed as luminosities using $M_r = -2.5 \log_{10}[L/L_\odot] + M_{\odot,r}$, where $M_{\odot,r} = 4.62$ (Blanton et al. 2001).

^b ϕ^* in units of $\text{Mpc}^{-3} \text{ Mag}^{-1}$.

computed with the V_{max} method of Schmidt (1968) explained in Sec 5.1, where the estimated LF value at each magnitude bin is the sum of the weights of all galaxies in that bin, with $w_i = V_{\text{max},i}^{-1}$. Table 4 contains the fitting parameters, choosing the fitting functions to be:

- Double power-law:

$$\Phi(L)dL = \phi^* \left(\frac{L}{L_*} \right)^\alpha \left(1 + \xi \left(\frac{L}{L_*} \right) \right)^{-\frac{1}{\xi}} \frac{dL}{L_*}, \quad (3)$$

granted that $1 + \xi(L/L_*) \geq 0$. This double power-law fit (Alcaniz & Lima 2004) collapses when $\xi = 0$

FIG. 8.— Luminosity functions of the $\{L_i\}_{i=1}^{20}$ groups ordered by increasing arc-length (blue triangles with a dashed line fit from Table 4). The aggregated luminosity function of all the L_i samples is shown as black circles with the Schechter fit as a black continuous line. The red diamonds denote the luminosity function belonging to the group of red galaxies located very close to the principal curve within the L_{20} group (see Sec. 6.5.2).

into the Schechter fit (Schechter 1976) $\Phi(L)dL = \phi^* (L/L_*)^\alpha \exp(-L/L_*) dL/L_*$. The ξ parameter can be related to the tail index in extreme value statistics (e.g Gumbel 1958; Galambos 1978), defining for the brightest luminosities an infinite reaching power law tail ($\xi > 0$), exponential tail ($\xi = 0$) or a cutoff at a finite maximum luminosity $L_{max} = L_*/|\xi|$ ($\xi < 0$).

- Log-normal:

$$\Phi(L)dL = \frac{1}{L\sigma_L\sqrt{2\pi}} \exp\left(-\frac{(\ln L - \mu_L)^2}{2\sigma_L^2}\right) dL \quad (4)$$

Note that a Log-normal distribution in luminosity-space is equivalent as a normal-Gaussian distribution in magnitude-space.

The luminosity function of the whole sample is well fitted by the Schechter fit, except for the bumps at the high luminosity tail and at the low luminosity end starting at $M_r \sim -18.8$, also observed by Blanton et al. (2003) and Blanton et al. (2005). We fitted it right before the bump.

The changes in the behavior of the luminosity function along the P-curve are determined also by the 3 turning points. In summary, M^* becomes fainter in

the 1st branch, and then brighter afterward. On the other hand, the slope of the faint tail behaves similarly to $\mathbf{PC}_2$. In fact, it is steep in the 1st branch, and becomes shallower in the 2nd branch, then again steep in the 3rd branch. The 4th branch contains an extremely shallow slope, where the luminosity functions resemble mostly a log-normal distribution. We can see that we recover the luminosity function shapes shown in Binggeli, Sandage & Tammann (1988), which are based on morphological types, and vary between schechter fits (as in L_1 to L_{15}) and bell shaped luminosity functions fitted by Log-normal fits (such as the L_{19} and L_{20}).

As we progress along the 1st branch of the principal curve (L_1 to L_6), the blue compact dwarfs become less luminous on average, having M^* dimmer in about $\Delta M^* \simeq 2$, with a mostly constant steep faint-end ($\alpha \sim -1.55$). Note that these galaxies, and mostly the low surface brightness spirals at the 1st turning point, create the bump seen in the overall luminosity function. In fact, L_6 contains the faintest galaxies in our sample (Fig. 6). At this point, $\alpha = -1.69$ gives the steepest power law slope at the faint luminosity tail. Note that this slope is expected to reach $\alpha \simeq -1.5$, as noted in Blanton et al. (2005).

In the second branch (L_7 to L_{13}), the star forming spirals present a faint-end that flattens dramatically and

starts to drop continuously, with an increase of $\Delta\alpha \sim 1.6$ from L_7 . At the same time, they start becoming much more luminous, with M^* brightening in $\Delta M^* \sim -2.2$ (from L_6).

In the 3rd branch (L_{14} to L_{17}), for the red spirals and lenticulars M^* continues becoming brighter ($\Delta M^* \sim -2.5$), but at the same time the faint-end slope starts turning steep again ($\Delta\alpha \sim -1.6$), back to the values of $\alpha \sim -1.6$ found at the end of the 1st branch. Note that L_{16} (green maximum) and L_{17} (red maximum) show long power-law faint ends with a sharp cutoff at the bright end. They are better fitted by a double power law fit, and since $\xi < 0$ they present bright-end finite cuts at $M_r \sim -23.0$ and -23.3 respectively.

The 3rd turning point (L_{17}) is a unique case. The luminosity function presents 3 power-law-like sections, the faintest one being flat. We attempted to fit it with a Schechter profile.

In the last 2 groups (L_{19} and L_{20}), the faint end tail has dropped enormously. We attempted a Log-normal fits for the luminosities, since the luminosity functions look more bell-shaped, specially the ones belonging to the $\{\lambda_i\}_{i=1}^{i=5}$ groups that track the spine.

6.4. Galaxy clustering

In this section, we investigate the second moment of the galaxy distribution as a function of the arc length, the spatial distribution, quantified by the clustering. We explore here not only the dependence of the galaxy clustering as a function of L , but also the relative distribution of galaxies as a function of L , which can be quantified by the cross-correlation function.

Following common practice, we compute first the redshift space correlation function, as a function of the distances parallel (π) and perpendicular (r_p) to the line of sight. We use a generalized version (Szapudi & Szalay 1998) of the Landy & Szalay (1993) estimator

$$\xi(r_p, \pi) = \frac{D_a D_b - D_a R_b - D_b R_a + R_a R_b}{R_a R_b} \quad (5)$$

where the subscripts a and b refer to the two samples we are considering when measuring the cross-correlation function. We use the same methods than Heinis et al. (2009) to compute the correlation functions. In brief, for each sample we generate random catalogs following the SDSS footprint defined by its sectors. We use 50 times more random objects than galaxies. We reproduce the selection function by randomly drawing redshifts from the current sample. We correct from fiber collision using the method described in Heinis et al. (2009). Note that the fiber collision correction applies only to the $D_a D_b$ term in Eq. (5).

As $\xi(r_p, \pi)$ is sensitive to redshift distortions, we consider the projected spatial correlation function afterward, which is free from such effects:

$$w_p(r_p) = 2 \int_0^{\pi_{max}} \xi(r_p, \pi) d\pi \quad (6)$$

where we use $\pi_{max} = 25\text{Mpc}$, for convergence purposes.

We compute error bars on $w_p(r_p)$ from jackknife resampling. We build jackknife samples using the SDSS

stripes, which are defined to be 2.5 degrees wide great circles on the sky, following the survey latitude. In practice we consider 23 jackknife samples built from the stripes.

We use a volume limited sample extracted from our main sample (see Sec. 2). In order to maximize the signal-ratio of the clustering measurements, we do not use 20 samples in L , but 8 of them built the following way: we collided L_1 to L_6 in two groups of similar number of galaxies (L_{w1} and L_{w2}), L_7 to L_{10} in one group (L_{w3}), and for the remaining L samples, we grouped them two by two ($L_{w4} = \{L_{11}, L_{12}\}$, $L_{w5} = \{L_{13}, L_{14}\}$, $L_{w6} = \{L_{15}, L_{16}\}$, $L_{w7} = \{L_{17}, L_{18}\}$ and $L_{w8} = \{L_{19}, L_{20}\}$).

Figure 9 shows the results for the auto correlation functions of these sample in the diagonal plots. As a reference, we show as solid line in all diagonal plots the auto correlation function of the sample with highest arc length (L_{w8}). The results from the auto correlation function show that the amplitude of the correlation function at large scales ($r_p \sim 10$ Mpc) increases with the arc length. This implies that the host halo mass also increases with l . This result is expected as l does correlate with $u - r$ and $g - r$ colors for instance. It is indeed well known that the amplitude of the correlation function increases for redder objects in the local Universe (e.g. Zehavi et al. 2005, 2011). There are also some interesting features in the small scales ($r_p < 0.1$ Mpc) clustering. Indeed, most samples show clustering power at all scales, except our groups 2 and 3 in particular, where there is an indication of a lack of pairs at $r_p < 0.1$ Mpc, suggesting a population mainly composed of central galaxies.

In the off-diagonal plots, we show the cross-correlation functions between these samples. It is beyond the scope of this paper to fully interpret all these measurements with Halo Occupation Distribution models (e.g. Cooray & Sheth 2002). We will use simple arguments to highlight the information contained in the cross-correlation function.

We represent as a solid line in all off-diagonal plots the expected cross-correlation function given by

$$w_{X_{ab}}(r_p) = \sqrt{w_a(r_p)w_b(r_p)} \quad (7)$$

where $w_a(r_p)$ and $w_b(r_p)$ are the autocorrelation functions of samples a and b . Eq. (7) gives the cross-correlation function which is expected in the case where galaxies from the two samples are well mixed in the dark matter halos hosting them (see e.g. Zehavi et al. 2005). This is of interest at small scales, where the cross-correlation function contains information about close pairs of galaxies that lie within the same dark matter halos. Our results show an interesting trend in this context. Indeed the cross correlation function of galaxies with close arc lengths is similar to the expected cross correlation function from Eq. (7). On the other hand, the cross correlation of galaxies more distant in terms of arc length diverges from the expected correlation function. In particular, the measures are *overestimated* by Eq 7 at scales $r_p < 0.1$ Mpc. This means that there are less close galaxy pairs in the measures than what is expected in the case of a perfect mix between galaxies of different arc length. Note that there is still clustering signal at these scales, which means that there are some

FIG. 9.— *Left*: The diagonal panels show the auto correlation function of the $\{L_{wi}\}$ groups. The solid black line is the auto correlation function of L_{w8} shown for reference. Off diagonal panels show the cross correlation functions between the groups, where the red solid line represents the expected cross correlation function when the galaxies from the 2 samples are well mixed in the dark matter halos. *Right*: Same layout as in figure on the left, but showing the ratio between the measured cross correlation function to the expected one when the galaxies from the 2 samples are well mixed in the dark matter halos.

galaxies belonging to distant L groups in the same dark matter halos. However, our results show that there are fewer pairs than what is expected if galaxies are properly mixed. This suggests that the probability that two galaxies reside in the same dark matter halo decreases as a function of their distance in arc length.

6.5. Interesting Galaxy Groups found from WPCA and Principal curve classification

The analysis of galaxy properties with WPCA and P-curve methods allowed us to find and pinpoint some relevant groups that stand aside from the main trends of the whole galaxy sample. In particular, here we pay attention to the small blob of galaxies that clusters apart from the main cloud in Fig. 2. Another interesting task is to isolate a *pure* population of red galaxies in the L_{20} group whose luminosity function is Log-normal, as it appears in Fig. 8.

6.5.1. Blob of small red disk galaxies/lenticulars of high M_*/L_r and $\mu_{*,50}$

In Fig. 2 we found a small blob of galaxies clustered apart from the main cloud in the $\mathbf{PC}_3$ v/s $\mathbf{PC}_4$ panel. We separated them by using the following separating line (built by eye): $\mathbf{PC}_4 \leq -1.3 + 0.55(\mathbf{PC}_3 - 2.0)$. We further constrained these galaxies by choosing an appropriate interval in arc length $[l_{min}, l_{max}] = [11.6, 12.6]$, which includes most of the L_{18} and part of L_{19} groups. In fact, the blob appears also in Figure 6 bracketed within this arc length range in the R_{90r}/R_{50r} , $\mu_{*,r}$ and $\log R_{90r}$ panels. Precisely, R_{90r}/R_{50r} is the property that dominates in $\mathbf{PC}_3$ and $\mathbf{PC}_4$ with opposite signs, as shown in Fig. 1. After the selection cuts, we are left with 136 blob galaxies, whose imaging and average spectrum are shown in Fig. 10.

According to Table 3, the blob is composed mostly by small red disk galaxies, with minimal star formation and void of gas. In fact, $u - r$ is at least 1σ redder than the average in the L_{18} group. Furthermore, they are modeled with an important component of an exponential disk ($\text{fracDev}_r = 0.00^{+0.48}_{-0.00}$). The concentration index $R_{90r}/R_{50r} \simeq 1.95$ is low and far from

FIG. 10.— Equivalent to Fig. 5, but showing interesting groups derived from WPCA and P-curve analysis.

Top: Panels with the 4 most representative galaxy shapes for the small red disk-like galaxies blob (*left*) and red spine galaxies (*right*).

Bottom: Average spectrum for the 2 previous groups.

the often used $R_{90r}/R_{50r} = 2.6$ separator between ellipticals and spiral galaxies (Strateva et al. 2001). The average size of $R_{90r} \simeq 1.6\text{kpc}$ is small compared to the one of L_{18} ($R_{90r} \simeq 4.0\text{kpc}$), lying beyond the 1σ significance level. Interestingly, the small size makes $M_*/L_r \simeq 4.07 M_\odot L_{\odot,r}^{-1}$, $\mu_{50,r} \simeq 18.83 \text{ mag arcsec}^2$ and $\mu_{*,r} = 10^{10.06} M_\odot \text{kpc}^{-2}$ to be also well above 1σ of their average at L_{18} . With respect to the uncertainty of these

values, errors in the estimate of M_* can arise when fitting the spectra, specially when there is a strong component of dust, which these galaxies appear to have. The statistical error in M_* is around 15%. When comparing to a catalog of groups from Tago et al. (2010), we found that at least half of these galaxies are in groups of more than 10 members. We speculate that they were depleted of gas by ram pressure stripping or another mechanism that did not perturb the structure of the disk.

6.5.2. Close-to-spine Red galaxies of Log-Normal luminosity function.

In Fig. 8 we showed that the L_{20} group of red galaxies has a luminosity function close to a log-normal distribution, clearly different to the Gamma and double power-law distributions of the other groups. For further study, we wanted to isolate the galaxies in this group whose luminosity function is exactly log-normal.

In order to extract these galaxies, we choose the ones falling in $\{\lambda_{98}, \lambda_{99}, \lambda_{100}\}$, which are the last 3 subgroups of L_{20} as explained in 5.3. We further chose the 1st partition closest to the P-curve, out of the 10 radial partitions in each λ_i group, selecting therefore galaxies on or very close to the spine of the data point cloud.

The selected red spine galaxies are part of the very high density core of the red sequence of galaxies found in L_{20} . In fact, Table 3 and Fig. 6 show that they have very similar properties values as their averages of the whole L_{20} . They are mostly red ellipticals ($u-r \simeq 2.62$, $\text{fracDeV}_r \sim 1$ and $R90_r/R50_r \simeq 3.23$), of mass $M_* \simeq 7.08 \times 10^{10} M_\odot$ and luminosity $L_r \simeq 2.86 \times 10^{10} L_{\odot,r}$. Figure 8 shows that the luminosity function of is in fact very close to log-normal, with parameters shown in Table 4.

7. DISCUSSION

The unsupervised non parametric methods of WPCA and P-curve should not be considered useful only for dimensionality reduction and easy data visualization. In this paper, these methods proved also being able to provide supporting evidence for some physical models and scenarios relevant in extragalactic astronomy, as discussed next.

7.1. Information Content of the Principal Curve

The principal curve provides an objective way for ordering galaxies along its arc length. The success in dimensionality reduction and classification power of the P-curve is related to how much the projections of the galaxies are spread along arc length. In fact, a big variance along arc length gives more room for building separators and discerning different galaxy types. In our case, the arc length values along the P-curve have a variance of $\sigma_l^2 = 7.79$ (see Table 2), bigger than cumulative variance $\Sigma_{i=2}^{i=4} \sigma_{\mathbf{PC}_i}^2 = 6.81$ of the principal components it was built from. This means that the curvature of the P-curve helps to discern information not included in the intrinsic linearity of WPCA. The length of the P-curve cannot be made arbitrarily long or short, due to an evident bias-variance trade-off. The shortest curves (with no curvature) are identical to $\mathbf{PC}_1$, with an average spread across it equal to $\Sigma_{i=2}^{i=p} \sigma_{\mathbf{PC}_i}^2$, and a high bias due to the straight P-curve missing the important bends in the structure

of the cloud of points. On the other hand, the longest curves possible would be the ones connecting all the data points, which produce a null bias but high variance, as the curve will fit the noise in the structure of the cloud. In fact, as we experimented with values of $df \simeq 7$, the curve attempts to cover all the space spanned by the cloud, twisting and coiling itself in ways that describe additional detailed features of galaxies, while we are now interested in the global trends. Our election of $df = 5.4$ is an intermediate case, where the root mean square of the projection distances on the curve is $d_\perp = 1.31$, smaller than $(\Sigma_{i=2}^{i=4} \sigma_{\mathbf{PC}_i}^2)^{1/2} = 1.52$. The ratio $1 - \sigma_l^2/d_\perp^2 = 0.75$ gives us a notion of the amount of information that the P-curve is able to discern. The physical origin in the scatter of the remaining 25% is still to be explored, and depends locally on the direction in the eigenspace along which $d_\perp$ is measured.

7.2. Explaining the Zoo of Galaxies

In our analysis, the P-curve has been able to recover the well known bimodality between the blue and red populations. Since galaxy properties are highly correlated, only a few properties should be enough for explaining the variations in the zoo of galaxies, namely $u-r$ (from $\mathbf{PC}_1$), SFR (from $\mathbf{PC}_2$) and less importantly $R90_r/R50_r$ (from $\mathbf{PC}_3$). In fact, the variations recovered by the P-curve and its "W" shape depend strongly on SFR . The color $u-r$, almost linearly correlated with arc length, tracks specifically the 4000Å break in the continuum, which gives a measure of stellar age and separates the early to late galaxy types. However, this is not enough, as $R90_r/R50_r$ tells about morphology, whereas the SFR tracks the amount of material produced in recent star bursts, which shows as the strength of emission lines such as the Balmer series, and eventually correlates with the galaxy size, mass and luminosity. For example, within the blue population (bluer than the green maximum) we can find the low star-formation and surface brightness spiral galaxies separating the bluest star-forming spheroidals/irregulars and the redder star-forming spirals with a prominent bulge. The importance of the color and emission lines from star formation in explaining variations in galaxy populations has also appeared in previous PCA studies (e.g. Yip et al. 2004b; Coppa et al. 2011; Györy et al. 2011).

7.3. Additional Evidence supporting some Physical Models

7.3.1. AGN Activity and Star Formation Quenching

The P-curve presents a green density maximum, between the blue and red ones. The green maximum shows an interesting feature in $\mathbf{PC}_1$ (Fig. 4), colors and M_*/L_r as a function of arc length (Fig 6). The average of these properties keep on increasing as the arc length increases, except at the green maximum in L_{16} , where they stay constant or even decrease their values. This behavior, however, is not seen for example in SFR/M_* , whose average continues decreasing monotonically at L_{16} . Note that L_{16} is the last group which shows significant star formation and/or emission lines (see Fig. 5). Indeed, the equivalent width of H_α drops by 1 dex (see Table 2) when moving to L_{17} , this last group is consistent with no H_α emission given the 1Å resolution of SDSS spectra. Fur-

thermore, L_{16} is the last group in the pure star forming region branch on the BPT diagram (Fig. 7), right before the bordering region separating the pure star forming and composite regions. Thus, higher arc length groups have basically small to null star formation activity and contain AGN. This is in agreement with the findings that AGN activity might be the cause for the shutdown of star formation in these galaxies (Martin et al. 2007).

7.3.2. Hierarchical Model of Galaxy Formation

The luminosity functions shown in Fig. 8 can be classified into roughly gamma and log-normal distributions. It has been shown, e.g. Cooray & Milosavljevic (2005) and Yang et al. (2009), that the LF of the Schechter fit for LFs can be divided into several components, coming from 2 different populations in dark matter halos: central or brightest cluster galaxies (BCGs) and satellite galaxies. Satellite galaxies are often given a power law LF, with a finite cut at the bright end given by the luminosities of the central galaxies. The centrals, on the other hand, are given bell-shaped luminosity functions. In particular, high mass halos ($M_h > 10^{13} M_\odot$, according to Cooray & Milosavljevic (2005)), contain central galaxies whose luminosity functions can be modeled as a log-normal distribution. This is exactly the behavior observed for the L_{19} and L_{20} groups in Fig. 8, and better seen for the red spine galaxies shown in Sec. 6.5.2. Note that L_{19} and L_{20} corresponds to L_{w8} in Fig. 9, which appears having an autocorrelation function with stronger power at $r_p = 10$ Mpc than any other group. On the other hand, at $r_p \lesssim 0.1$ Mpc there is a clear loss of power. This is consistent with L_{19} and L_{20} being mostly composed by central galaxies. Note that there is still power in the autocorrelation function of L_{w8} at $r_p < 0.1$ Mpc, which shows that there are some satellite galaxies (mostly red) in this sample, which is consistent with the faint end tail of the LFs in Fig. 8.

Log-normal distributions appear in nature as a consequence of multiplicative processes (Lempert et al. 2001; Mitzenmacher 2003, and references therein), where the initial value Y_0 of a random variable is changed in successive steps in the form $Y_j = F_j Y_{j-1}$ by i.i.d multiplicative factors F_j of distribution $P(F)$. Using the central limit theorem for $j \rightarrow \infty$, it can be shown

that Y follows a log-normal distribution, independent of $P(F)$. This argument can be extended to explain the log-normal luminosity functions of central galaxies and their stellar mass functions as well, since the r-band luminosity traces a population of old stars, which form the bulk of the mass of galaxies (Bell et al. 2003). In fact, hierarchical galaxy formation models (e.g Steinmetz & Navarro 2002; De Lucia & Blaizot 2007) explain the creation of massive elliptical BCGs as a series of dry mergers of existing galaxies. Thus, a dense environment will allow several steps of mass adding or stripping that might lead to the formation of BCGs and cause the log-normal mass distributions for them.

MTP acknowledges the use of the VO spectrum service for averaging galaxy spectra (Dobos et al. 2004), and thanks Ching-Wa Yip, Mark Neyrinck, Timothy Heckman and Sean Moran for useful discussion. The authors thank the anonymous referee for advise directed to enhance the impact of this paper.
